INTRODUCTION

Maise, (Zea mays, L.) belongs to the family Graminese and is cultivated all over the world. Various theories have been proposed to account for the origin of this plant. Recent discoveries of fossil maise pollen by Barghoorn and his collaborators (1964) have established the existence of this plant in Maxico, much earlier than the most primitive type of agriculture known to have existed anywhere in the western hemisphere. In India the maise has been grown since early days of 17th century.

The cytological studies have established Mexico, and Central America as the centres of origin of maise. In nature the maise plant is diploid having 2n=20 chromosomes. It is the only species of genus "Zee".

In India maise plant is known by various names as "Makai", "Maka", or "Comdhan". Among cereals this erop occupies the 4th position from cultivation point of view. In 1962-63 the total accrege under maise was

11,316,000, with a total production of 4,449,000 tonnes. An average yield being nine mds. per acre. In Rajasthan it is grown in 1,670,600 acres of land and total production is 694,777 tonnes. Out of this 4,00,490 Acres of land is cultivated in Udaipur district alone and produces 208,444 tonnes of grain. The average yield of maize is also higher in this area being eleven mds. per acre.

Mains has been put in various usages. It is consumed by human beings, used as cattle feed and is also utilized in the industrial purposes for the preparation of starch, yearn, alchold, paper and various plastic materials and many other commercial products.

In India maize is highly hetrozygous material. Recently a lot of work has been taken up to improve this crop. The systematic steps towards the improvements of the crop were stressed by Sir P.M. Khareghat in 1943, and I.C.A.R. Schemes were started all over India for maize breeding programmes. Some materials of hybrid maize have been released for commercial purposes which gives 26-30% higher yield over the local one and is early maturing.

The yield, which in itself is not a unitary character, is the result of interaction of a number of factors both heritable and environmental. Thus it becomes essential to study the various characters and find out their effects on the yield. This type of study is facilitated by the use of Correlation studies.

The present work has been done to study:

- 1) The total Coefficient of Correlation for different characters between the Parents and their Figens-rations.
- 2) The partial Coefficient of Correlation for different characters which make contribution on yield.
- 3) For the production of yield, good combiner parents have been evaluated by General and Specific combining ability, as used by Sprauge & Tatum, (1942).
- 4) The characters showing heterosis.

review of Literature

weluminous literature is available on maiss erop, specially regarding correlation studies, laterosis and Combining ability. The present review have been done on quantitative characters of the plant. The knowledge of the relationship between the various attributes of inbred line and their F₁ hybrids is considered to be useful in selection of the parent. The study of the combining ability for proper selection of the material, directly helps in rejecting the poor performens at an early stage, thus helping in saying labour and expenditure. A brief review of the study of heterosis is also reported.

erop were based on selection of superior cars from open pollinated material, as such, the plant characters were naturally related to the proper yield. Ath the help of development of hybrid mains, the importance of correlation studies has increased transndeously.

Swing (1910) found the negative coefficient of correlation i.e. (-0.202) between yield and days to milk, and positive correlation among the height of the plant and to yield (+0.307).

between yield and days to tasseling and days to silking. This indicated that the plant flowering late within a given variety produces less grains than the early flowering plants. He also found the high and significant values for the Cofficient of correlation between weight of grain and length of the cob viz. (+0.877 ± 0.008). In his opinion the diameter which he measured become an important indicator towards selecting high yielding corn.

Olson (1927) stated that tasseling and silking dates were reliable basis for comparing varieties for early maturing; and suggested that counts should be made after 1/4th plants had tasseled or silked, and not after 1/2 of the population had reached that stage.

Jenkins (1929) took 142 inbread lines of maize derived from 14 varieties and calculated 210 total Correlation Coefficient values. Out of these 65 were statistically significant. He reported positive correlation for height of the plant (+0.20), Cobs per plant (+0.31), Cob length (+0.38), and Cob diameter (+0.32) with yield.

Many of his findings were negatively significant in respect to yield and days to silking (-0.26). The correlation coefficient values between yield and days tasseling were also negative but not statistically significant (-0.230). He further reported that the presence of deliterious characters resulted in lack of vigour and low yields.

oters such as time of flowering (Tasseling and Silking) per centage of moisture in seeds, weight of the dry seeds were correlated among themselves, but the length of the cob was not found to be correlated with any of the above characters and concluded that earlyness in corn plant could not be judged by time of flowering, per centage of moisture in seeds and dry seed weight alone.

Hays & Jhonson (1938) carried out extensive studies on correlation involving certain characters of inbred line with those of their carosses. They reported that date of silking had the correlation value of (+0.4748) with yield, whereas Plant height had (+0.2717) and Cob length (+0.2758) with yield.

Kempton (1926) using the varieties Algeria x Jala as parents made certain correlation studies in maix hybrids. He noted in F_1 hybrids that early flowering (Tasseling and silking) varieties were more productive but could not establish the same results in F_2 crosses.

Hotchison & Wolfe (1918) found little relationship between weight of grains and other characters of the plant like tasseling and silking dates.

weihing (1935) found the height of the plant, number of green leaves per plant and vigour of the plant were correlated with lateness in the maturity of the crop.

craige (1908) found that yield of the plant was less correlated to those characters which influenced the vigour of the plant and vegetative growth viz.

height of the plant, number of nodes and inter-nodes per plant and also green leaves per plant.

Davenport (1907) reported highly positive significant correlation value for langth of the cob, dismeter of cob, with respect to yield, i.e. (+0.87), and (+0.47) respectively.

Jorgenson & Brewbaker (1927) studied relationship between certain ear characters of Inbreds and their Crosses. They obtained positive significant correlation value for various characters, viz. height of the plant, cob length, cob diameter with the yield.

Nilson Leissner (1927) found that certain inbread lines were distinctly superior to others as parent.

as well as Crosses. He found that coefficient of correlation between yield and height of the plant was positive and significant in F₁ crosses. Similar results were reported by Hays (1926). He found significant correlation with height of the plant and ear length with yield. He also observed that Crosses with high yielding strains usually gave better results than crosses with low yielding strains.

Richey (1925) found that there was a positive correlation in length of the ear, height of the plant with yield and found a negative correlation with yield and Kernel rows numbers. He said "To judge the relation productiveness of good ears on the basis of their appearance is not warranted".

plants in relation to vegetative growth and found it to be positively correlated. He also found a positive correlation value for green leaves per plant and 100 grain weight with the yield, however, he could not find any correlation between time taken for maturity, length of the cob and cob diameter with yield.

Keller (1942), in a 2 double crosses and 4 single crosses of maise observed that length, dismeter and height of the plant to be strongly positive correlated with yield of the plant.

As early as 1896 Brigham's working with yellowflint type of maize, concluded that yields of the plant was associated with lesser number of leaves per plant and intermodes on it. His conclusions were not based upon statistical calculations.

Montogomery (1911), Love (1912), Mc Call & Wheller (1913), Williams & Welton (1915), Love & Wentz (1917), Brunson & Willer (1929), observed that there were no significant correlation between yield and length of ceb and height of the plant.

Montogomery (1911) reported that ears with greater length produces better yield, however, the size of the ear was dependent upon environmental factors.

Furwirth (1904) reported that ear with greater length was directly correlated with weight of the grain and yield. He worked out this findings with Szelker Corn.

Cunningham (1916) divided the maise varieties into various groups according to ear size. He stated that correlation between yield and cob length was not significant.

Olson, Bull and Hays (1918) indicated that there were no well marked basis for using ear characters to determine the yield. They further found that positive correlation between length of the cob and yield. The results were not significant.

Lindstrom (1986) studied relationship of ear characteristics for 2 generations in the corsses with their parents. He reported that length and diameter of the cob had positive correlation with yield.

presented both phenotypic and genotypic correlation involving a series of attributes in the crosses for two generations. In few cases the two estimates of association differed appreciably. Cobs per plant, was the only character which showed high positive genetic correlation (+0.231) with yield but they obtained low values of 'r' in yield and other characters such as ear length as well as for the height of the plant.

Kepf (1953) noted and pridicted the values for 'r' for the length of the cob and diameter of cob when combined with yield in single crosses.

Murty & Roy (1967) studied 95 varieties of maize both indigenous and exotic in respect of different plant and ear characters. With a view to find out characters which were associated with yield high total correlation coefficient were observed between length of the ear and yield (r = +0.7600), 100 grain weight and yield

(r = +0.6667), yield and plant height (r = 0.3296).

Partial correlation coefficient were worked out between yield and other characters as plant height, ear diameter, ear length and 100 grain weight. In yield plant height was involved and values for such correlation coefficient were very low.

Combining Ability:

prominent in transmitting high yields and other characters to their proganies in crosses. The lines which could transmit easily are known as good combiners.

The first idea regarding the combinging ability was given by Mc Clure (1892). According to Zirkle (1987) all inbred stock did not produce same amount of vigour.

Harrington (1932) suggested that enalysis of a character which can be studied in Y2 population would provide a means of pridicting the values.

inbreds were better combiners then others as were apparent from higher yielding ability studied from hybrid progaines. The problem of evaluation of maise inbreds from their combining ability point of view has been tackled from two different angles. Firstly, by establishing the correlation between characters of inbred and their F₁ crosses produced (Kiesselbach 1922, Milsson Leissner 1927, Jorgenson & Brewbaker 1927, Jenkins 1929). They considered that correlation values were heritable characters, however the real evaluation of mains inbred line could be studied by actual hybrid progenies only.

Jankins (1936) concluded that the combining ability of inbreds become fixed in the inbreding process and that future selection had little influence on it.

The procedure for evaluating the inbred lines involves two steps:

- 1) General combining ability, and
- 2) Specific combining ability.

The term "General Combining Ability" is used to designate "the average performance of a line in hybrid combination". This was proposed by Sprauge & Tatum (1942). It is impracticable to test the line as such till their single and double crosses were not produced. Several investigators have reported data bearing the point Kiesselbach (1922) found a general relation between the yield of inbred line and of their habit hybrid combination. Richey & Coworkers (1947) advocated a series of inbred testers for determining the general combining ability of inbred line. Jenkins and Brunson (1932) grouped the inbreds and tested their

performance in inbred variety cross, as well as in series of single corsess. They took 9-12 inbred lines in each group. Jones (1922) prior to Devis worked on inbred variety corosees, but his interest in such crosses was from the stand point of commercial utilisation of these grosses rather than as a method of evalusting inbred lines. Lindston (1931) also carried out extensive experiments on inbred x variety cross but his aim was also to find out, if such crosses could be useful commercially. He used inbred lines (56) as a male parent and commercial variety as a female parent. IB noticed a marked propotency of inbred series for ear type, disease resistance, lodging resistance, and uniformity a in maturity. His results showed significant interest in yield from such crosses but credit want to Jenkins & Brunson (1932) for the series study to find out if a variety could be substituted for a series of inbred testers and results had led to the wider acceptance of the top cross method for the rapid evaluation of new inbred lines. They used 202 inbred lines divided into 5 groups based on early and late types, white and yellow seeded type and inbreds from differnet localities. Trials conducted at 2 places in different years correlations were studied. They considered that inbred variety corosees would seem to be real promise in pridicting the performance of lines in single crosses. They suggested that this should be performed economically in an isolated

plot.

combining ability as the "Average merit with respect to some trait" or "weighted combination of trait of an indefinitely large numbers of progeny of an individual" or "line when mated with a random sample from some specified population". He further stated that general combining ability had no meaning unless its value was considered in relationship to atleast one another individual or line under specific conditions.

Payns & Hays (1949) tested, selected inbred lines in F₂ & F₃ generations from the cross of All6 x L317 with 4 inbred testers. Data were analysed for yield and for moisture per centage. Statistically significant difference in yield in F₂ & F₃ lines were obtained. The significant difference were noted in plant within families. They showed in F₃ lines produced desirable plants in combining ability. They also found that low yielding F₂ families gave lowest yields in F₃ erosses.

Hull (1947) assumed that better inbred lines already employed in commercial use were worthless as testers for General combining ability because of their tendency to observe difference among lines under test.

Green (1948), Keller (1949), Richey (1950)
Mestringer (1953) have also provided the tests for General
combining ability for inbred lines of maize.

Green (1948) emphasized a synthetic variety made up of line currently used would be the best tester for measuring the general combining ability of new inbred lines. Keller (1949) compared a related and an unrelated single cross as a tester parent in evaluating a group of selected F_2 plants from a single cross. He found 2 tester did not gave similar measure of combining ability.

Richey (1950) stated that combining ability of new imbred lives could be known more parfectly by their crosses and more single crosses could be used. He also considered that no one variety was likely to provide an unbiased test for all.

of inbred lines, single crosses and double crosses as tester parents. He selected 8 inbred lines for hybrid production and utilized the same 8 lines to form 4 single crosses and 2 double cross testers. His data suggested that rank of General combining ability could be accomplished most economically through the use of a tester having a broad genetic base. He considered that selection of a line for replacement of an existing line in double cross combination would be a best tester.

Rojas (1951) had developed a mathematical model for estimating the variance for general and specific combining ability from groups of single crosses and observed that estimates of relative magnitude of variance of General and Specific combining ability from individual experiment was of limited value.

Sprauge & Tatum (1942) attempted to differentiate between general and specific combining ability by analysis of varience method. The data for all the possible combinations of yields within a group of inbreds were recorded. The lines which were tested previously had greater variance for general combining ability, however, those lines which were not tested previously showed a poorer variance for general combining ability and these results were based with assumption that general combining ability was dependent upon additive geneic effect while the specific combining ability was dependent upon Epistic.dominance and other effects. The large values for variance for general combining ability may arise because of line is either much better or much poorer than the remaining lines with which it is compared. Thus it provides indication that it is additive in nature. Low values for Gos indicate that hybrids involving this particular line has performed as would be expected on the basis of General combining ability. High values for variance for specific combining ability indicate

that some combination did relatively better or poerer than expected.

Lonnquist (1950) concluded that early testing of S₁ lines or S₀ plants in top cross provided a more efficient test of combining ability and provide a better basis of selection than the visual methods.

experiments to find, if high combining S_1 lines as determined by top eross test would gain in combining ability. For the first time in India Singh (1955) compared General Combining ability between S_1 , and S_2 , S_2 and S_3 and S_4 and S_5 lines in top crosses. The characters studied were yield, shalling per centage, days to tasseling, moisture per centage, plant height, ear height, number of good ears per plant, ear grain weight, 100 grain weight. There were no significant difference in all these comparisons except for days to silk, days to tassel, in S_3 and S_4 comparisons and these were as 5 per cent level.

Specific Combining Ability:

The term specific combining ability is used to designate those cases in which certain combinations do relatively better or worse than would be expected on the basis of average performance of the line involved.

As defined by Sprauge & Takum (1962) to the "Actual yielding capacity or ability of an inbred when erossed with another inbred in specific combination".

ability as the deviation of the average of an indefinitely large number of progeny of two individuals or lines from the values which would be expected on the basis of known general combining abilities of these two lines or individuals and the maternal ability of the female parent.

Rolas & Sprauge (1952) observed that estimates of the relative magnitude of the variance of general and specific combining ability from individual experiments might be of limited value. The point of major interest was the constancy of such estimates when such experiments were repeated over a series of locations or years. When the estimates for General and Specific combining ability were obtained from individual experiment the results were in agreement with the results of Sprauge & Tatum (1942). However, when estimates were obtained over all years and all locations they were of essentially of equal magnitude. The interaction of General and Specific combining ability were considerably smaller than corresponding interaction involving Specific combining ability. These findings seemed to hold true for both previously tested and untested lines.

Shall (1909) advocated that after producing the reliable homosygous lines through confined inbreeding those should be tested for yield in all possible single excess. The similar view was stressed by Hays (1926) who stated that after obtaining selfed lines the study of their performance for yield in F₁ crosses was a logical step. Sprauge & Tatum (1942) presented the work of fundamental importance on the nature of two kinds of combining ability and clearly differentiated between them on the basis of gene action involved. They made a study of relative importance in 45 single crosses of maize derived from ten inbred lines.

Gowen (1952) emphasized the importance of genotypic environmental interaction as the factor for determining the variance for General and Specific combining ability.

HETEROSIS:

The various aspects of heterosis or hybrid vigour have probably received more attention by plant geneticists and plant breeders than other single subject. The phenomenon of "Heterosis" hardly needs any introduction at present. Indeed the accdemic interest in the subject was evoked in early days of this century and high yielding hybrids were evolved in many crop plants including mains.

vigour of certain hybrids over the mean of the parents or over better parents had been recognised since the days of Koelreuter (1763). Independent studies were started in 1905 by East at the connecticut Agricultural Research Station and by Shull (1908) at cold spring harbour to understand the problem in maise.

The term "Heterosis" was first proposed by Shull (1914) to avoid the implication that all the genetypic difference, which stimulate cell division, growth and other physiological causes were mendelian in inheritance and to substitute for the term "Stimulus of heterosygosity".

A true picture regarding the theoritical basis of hybrid vigour has not yet been obtained.

Various theories from time to time have been forwarded to understand this phenomenon. The various theories are:

- A. Genetical explanations, and
- B. Physiological explanations

The genetical explanations has also been named as theory of dominance and over dominance (Jones 1910, Keeple & Pellew 1910, Bruce 1910, East & Shull 1936, Whaley 1944, and Hagberg 1953).

The mathematical studies were made by Bruce (1910), Keeble & Pellew (1910) to explain vigour in F₁ hybrids of Pea and they were the first to postulate the dominance hypothesis on the basis of additive nature of genes. All the dominant genes from the parents are contributed in the F₁.

payenport (1908) pointed out that dominant character is beneficial to the organisms while the resessive has the weakening effect to it. Jones (1917) upheld the dominance theory and gave the name as "dominance of linked genes hypothesis" and pointed out that a dominant gene might be linked with some determental researive gene to prevent isolution of an individual with all the dominant genes.

Studies of Richey (1927), Richey & Sprauge (1931), and of Murphy (1941) on maize had provided evidence that atleast some of the improvements in vigour by crossing inbreds was due to a number of dominant alleles, rather than to an increased heterosygosity.

Lonnquist (1953) provided evidence in favour of dominance theory by involving excess of High x High, High x low, Low x Low, combining lines in maise. From his studies he concluded that complementry game action of dominant genes played the role in development of heterosis.

Jones (1946), Castle (1946), and
Gusstafason (1947) had emphasized the importance of
allelic interaction to heterosis. Power (1944) presented the explanation of heterosis that he considered
heterosis and dominance were different degrees of
expression of some "Physiological genetic phenomenon".
It was apparent that dominance and partial dominance
were menifestation of heterosygosity. East and Hays
(1912) said if a hybrid was due to a number of dominant
favourable genes obtained from two parents than why not
same of the Fo showed the vigour equal to Fo.

Bull (1945) explained the cause of heterosis to be over dominance and concluded that heteroxygotes were between homoxygotes.

The theory of Physiological stimulation arose from the union of unlike gametes and was reported by Ashby (1996), lindstrom (1997), Sprauge (1996), Luckwill (1997), Peddick (1994) and Stringfield (1990). This aspect of heterosis had gained importance only since 1990 when Ashby (1990) published his findings on maize. Ashby's studies showed that hybrids had the same relative growth rate. He took two inbred lines of maize and their F₁ progamies and grow them side by side. He attributed the vigour of the hybrids on the greater embryo weight of the hybrids. He considered hybrid vigour in crosses

were nothing but more than the maintainence of great embryo size and stated this "Greater initial capital" hypothesis.

١

Lindstrom (1935) made a specific study of Ashby's hypothesis based on greater initial capital.

Be decapaciated the vigour F₁ seedlings to remove the initial advantage, but inspite of this reduction in capital, all the progenies in F₁ exceeded than their parental strains. Thus concluded that hybrids must have a higher growth rate than the parental inbred strains.

Sprauge (1936) observed that growth rate of hybrid was greater than that of Inbreds and during the first two phases of growth (Fertilization to maturity of seed and germination to smedling stage), but a higher growth rate was not established for 3rd stage viz.

seedling stage to fertilization. He concluded that hybrid vigour could not be attributed to the maintenance of initial difference in embryo size.

hybrid seeds showed a higher growth rate at initial stage but later no difference was noticed. Paddick (1944) studied two inbred lines of make and their hybrids. He found that hybrid which grow fast made over all great growth and were composed of large plant parts. He noticed that inhibitary effects of tassel and silk

formation were rapid in F₁ hybrid than their parents.

He concluded that "Hybrid vigour appears as a factor accelerating the growth activities of the plant and carry them to the point beyond which is common in less vigrous inbreds".

whaley (1950) reported that results of his study on growth rate of inbreds, single and double crosses of maise, in terms of fresh and dry weight increased during the genetication and at maturity period. No relationship was found between the size of the embryo and ultimate size of the plant. Hybrids were better than parents phenetypically as he concluded.

The manifestation of heterosis had also been reported in various self and cross pollinated crop plants vis. Sugarbeets, Sorghum, Cotton, grasses, Tomato, Cucumber, Eggplant, Onions, and many forage plants besides maize.

Conner & Karper (1927) studied heterosis in Forghum. F_1 generation gave 66 per cent taller plants than their tallest parents and in F_2 generations 40% of the plant showed taller plants than the tallest parents.

Hutchinnson (1947) indicated that good yields and wide adaptability of many commercial varieties of cotton were due to their appriciable betweeny-cosity maintained by cross pollimation.

Power (1946) obtained in tomatoes a very good relationship between parent yield of ten varieties and their possible F_1 crosses. Tysial Stal (1942) utilized the phenomenon of hybrid vigour in double and single crosses in alfalfa.

In India the study on the various crop plants have been done for heterosis. The studies made at I.A.R.I. by Pal etal (1950) on crops like maise, gram, seasemum; chillies, etc. should that most suitable plant utilization of heterosis was maise alone in the characters studied, were plant height, number of green leaves, number of days taken for emergence of tassels and milks. They noted that hybrids were taller than their parents and bore more leaves, Tasseled and milked earlier than their parents. They did not consider the gram plant suitable for this study due to difficulty in making the crosses on large scale and because of suspatability of plant to wilt disease.

manifestation of hybrid vigour in rice and had developed some of hybrid varieties. Solumn & Solumni et al (1969) studied morphological character of plant, like plant height, stem girth, 100 grain weight, and yield. Hybrids gave 25.87% to 201.13% higher yield over the superior parent. This was due to the sore population of number

of seeds per penials and increased seed weight in the hybrids.

In ease of each crops the hybrid vigour has been noted in respect of yield in Gossypium hirsutum and Gossypium barbadens by Choudhary (1947) and Santhanam (1951). They noted the growth in lint length, Ginning per centage and plant height. etc.

Rap & Menon (1951) have studied the heterosis on Bajra. Sikka and Swaminathan (1956) worked in wheat crosses. The heterosis was shown by the crosses involving in Indian varieties and south American like Rio, Negro, etc.

MATERIALS & METHODS

Seeds of 15 inbred lines, and their 45 single crosses produced at the Botanical Carden of Rajasthan College of Agriculture, Udaipur were taken.

Based upon the availability of F₁ seeds the 15 inbreds were grouped into three groups as given below. Each group had six inbreds and fifteen single crosses:

Group I : U wf9, U201, U202, U212, U301, U310

Group II : U203, U205, U207, U208, U215, U302

Group III: U Mr9, U201, U208, U200, U304, U307

The material was sown in randomised blook with three replications. The twenty plants from each having plant to plant 2' distance and row to row 3' distance were kept.

By dibbling method all the material was sown on 2nd July, 1963 in Botanical Garden of the College. 3-4 seeds per hill were sown after germination these were thinned to two plants per hill. Two border rows around the layout were sown, of the local material.

Characters studied were grouped into

(i) Maturity Group, (ii) Vegetative characters Group,

(iii) Oob and grain characters Group, and (iv) Yield.

Dutails of the procedure adopted for taking the observations were as follows:

1) Days to mid Tasseling:

The mid-tasseling of the crop is considered when 50% or more of the plants are in tassel. The first tassel was recorded when his it came out from the booth. Thereafter daily counting of tasseled plants were made till 50% plants tasseled.

2) Days to mid Silking:

The same procedure was scopted in taking down the observations as in the case of tasseling.

3) Days to Maturity:

The cobs completely dried and ready for shelling were considered to be mature. The exop was taken to be mature when 50% of the cobs were dry.

4) Height of the Plant:

Many methods have been adopted to measure the height of the maise plant. In the present study plants were measured from the grown to the tip of the tassel in centimeters. All plants of Inbreds and F_{1} 's were measured separately and than the mean was calculated.

5) Number of Green Leaves per Plant:

Leaves were counted starting with the flag leaf appeared and mean value of Inbred and F_{1} crosses were calculated respectively.

6) Number of Cobs per Plant:

on the total ears formed on the plant were counted, and then harvested separately for each inbred and F1 hybrid. Many of the ears did not bear any seed and such cabs were not considered as good cabs. A separate record was maintained for good and bad cobs respectively, however, both were considered while calculating the mean.

7) Ser Longth:

The cobs, when harvested were dried completely busked and then measured in centimeters from the bust end to the tip of spical end. All cobs from individual lines were measured.

8) Diameter of the Cob:

The diameter of the cob was measured with the halp of vernier calliper and meter scale leaving 1/3rd portion from the butt and in the husked cobs.

9) The weight of the 100 grain seeds:

The weight of the 100 grain seeds were taken when the cobs were shalled out. Ten samples of 100 seeds each from every line and F₁ cross were weighed and then mean value was obtained.

10) Grain yield per plant:

Notal seeds per plot divided by total number of plants in each plot gave the grain yield per plant in inbreds and F₁ hybrids.

The coefficient of correlation for the characters by true mean method were calculated in addition to that partial correlation coefficient have been worked out for the characters like Plant height, number of green leaves per plant, days to maturity of crop and finally yield per plant.

To study the hybrid vigour by comparison the mean value of I hybrids with the mean value of their parents and in the mean value of the superior parent have been calculated for aix characters of the plants were used:

- (1) Plant height, (2) Gob Length,
- (3) Cob dismeter, (4) Days to maturity of the crop.
- (5) 100 grain weight and finally (6) Yield per plant respectively.

Sprauge & Tabus (1942) method was used to find out the relative importance of variance of General and Specific combining ability for yield of inbred lines of the various groups separately by the formula proposed by them as under:

$$G^{2}a = \frac{n-1}{n(n-2)} - \frac{(\frac{n}{2}Ta-T)^{2}}{\frac{n(n-1)(n-2)}{4}} - \frac{R}{r}$$

n = Total number of Inbred lines in experiment

2 - Mean Square Arror

r = Number of Replications

Ta = Total of yield of inbred lines in the column

T . Grand total of the yield.

All the yield data are kept into two way table and then multiplied by (n-2).

Sa =
$$(n-2)$$
 (ab)-Ta-Tb+ $\frac{2}{n-1}$ T

Sa = $\frac{R}{r}$ + $\frac{(n-3)}{(n-2)}$ S = $\frac{\text{Square of yield}}{(n-3)}$ (n-2) (n-3)

Thus variance for all inbred lines are to be find out by this method.

EXPERIMENTAL RESULTS

The mean value of the various characters studied are given in table No. 1 and 2.

The Correlations among the various charaeters of Inbreds have been worked out (table No.3) and the results are summarised as follows:

Days to Tasseling:

Silking (+0.521), days to maturity (0.473), Oob length (0.080), Plant height (0.064), however, the value of 'r' for days to milking is significant at 5% level. The days to tesseling showed negatively correlated with yield per plant (0.334), grown leaves per plant (-0.213), cob diameter (-0.142), 100 grain weight (-0.120). The highest value of 'r' have been obtained for days to miking, days to maturity and yield per plant only.

Days to Silking:

This character is positively correlated with days to tasseling (+0.621), days to maturity of orop (0.261), and cob dismeter (0.024). Regatively correlated with yield per plant (-0.608), loo grain weight (-0.381), green leaves per plant (-0.344), plant height (0.231) number of cobs per plant (-0.031) and finally with cob length (-0.001). The 'F' value for yield was negatively correlated and found to be significant at 5% level.

Days to tasseling shows the maximum positive correlation.

Plant Hight:

The plant height is positively correlated with number of cobs per plant (0.531), weight of 100 seeds grain/weight (0.382), yield per plant (0.356), green leaves per plant (0.251), days to maturity \$9.221), sob dismeter (0.200), days to tasseling (0.064) and cob length (0.001). The characters cobs per plant is significant at 5% level. The plant height is also negatively correlated with days to silking (-0.231). Number of cobs per plant shows the highest 'r' yelus.

Number of Green Leaves per Plant:

This character has positive and significant value of 'r' for the weight of the 100 grains (+0.668), and number of cobs per plant (0.564). It is positively

correlated with plant height (0.251), yield per plant (0.262), and cob length (0.002). This is also negatively correlated with days to silking of the crop (-0.344) days to maturity of the crop (0.244), days to tesseling of the crop (-0.213), and sob dismeter (-0.041).

Number of Gobs per plant:

Inia is positively and significantly correlated with cob length (0.608), green leaves per plant
(0.564), Plant height (0.630), and positively correlated
with yield per plant (0.384), days to maturity of evop
(0.141), weight of the 100 grain seeds (0.071) and
finally with days to tesseling (0.850). Number of cobs
per plant are also negatively correlated with cob
diameter (-0.170) and days to silking of the evop (-0.081)
In this character cob length, plant height and green
leaves per plant are showing high values of coefficient
of correlations.

Cob Length:

This is positively correlated with number of cobs per plant (0.606), days to maturity of the crop (0.200), yield per plant (0.150), leaves per plant (0.002) days to tasseling of the crop (0.030), cob diameter (0.668), and with plant beight (0.001). Oobs per plant is however is a significant character. Oob length is negatively correlated with 100 grain weight (-0.713)

and days to silking (-0.001). The 100 grain weight is significant at 5% level.

Cob diameter:

maturity of erop (0.460), loo grain weight (0.414), plant height (0.800), cob length (0.088), yield per plant (0.039), and days to silking (0.084). This character is also negatively correlated with number cobs per plant (-0.170) days to tasseling (-0.142), and number of green leaves per plant (-0.041). However, the days to maturity has a slight higher value of 'r'.

weight of 100 grain seeds:

This character is positively and algnificambly correlated with green leaves per plant (0.668), and positively correlated with cob diameter (0.414), plant height (0.838), yield per plant (0.113), days to maturity (0.078), and cobs per plant (0.071).

The weight of the 100 grain seeds is negatively significantly correlated with cob length (-0.713) and only negatively correlated with days to alking (-0.391) days to tasseling (-0.120). The character shows maximum positive correlation with leaves of the plant whereas the cob length is negatively correlated.

Days to maturity of Grop:

This character is positively correlated with days to tasseling (0.473), cob dismeter (0.460), days to silking (0.252), Plant height (0.221), cob length (0.200), weight of 100 grain seeds (0.072), and yield per plant (0.001). This character is also negatively correlated with green leaves per plant (-0.244) and cobs per plant (0.141). Cob dismeter and days to tasseling shows high values of 'r' with days to maturity.

Yield per plant:

This character is positively correlated with cobs per plant (0.384), plant height (0.866), number of green leaves per plant (0.842), sob length (0.150), weight of 100 grain seeds (0.113), sob dismeter (0.033), and days to maturity (0.001). Now of the characters are negatively correlated with yield vis. days to silking (-0.608), and days to tasseling (-0.334). The 'r' value for days to silking is significant at 5% level.

The results for the correlation of coefficient studied enong the various characters in F₁ crosses have also been worked out (Table No.4) and these results have also been summarised as under;

Days to Tasseling:

with days to milking (+0.621), days to maturity (0.450) and only positively correlated with green leaves per plant (0.100). This character is also negatively significant with the weight of 100 grain seeds (-0.460), yield per plant (0.386), and plant height (-0.386), between, only negative correlation with cob diameter (-0.129), number of cobs per plant (-0.119) and cob length (-0.024) is reported. The days to milking is showing the maximum value of 'r' with days to tasseling.

Days to Silking:

orrelated with days to tasseling (0.621), days to maturity (0.855) and only positively correlated with green leaves per plant (0.085), also negatively significantly correlated with cob diameter (~0.724), weight of 100 grain seeds (~0.393) and negatively correlated with plant height (~0.279), yield per plant (~0.233), cobs per plant (~0.164), cob length (~0.090). However, in this case the days to tasseling, cob diameter, shows a very high degree of coefficient of correlation.

Height of the Plant:

This is found to be positively correlated with 100 grain weight (0.406), leaves per plant (0.280), and diameter (0.182), and length (0.178), yield per plant (0.169) and number of cobs per plant (0.166). The 'r' value for 100 grain weight is significant at 5% level. The few of the characters are also negatively significantly correlated with above characters like days to tasseling (-0.286) and negatively correlated with days to silking (-0.279) and days to makurity (0.068).

Number of Green Lasges per Plant:

This sharester is positively correlated with Plant height (0.220), number of cobs per plant (0.220) and 100 grain weight (0.220), cob length (0.220), yield per plant (0.205), days to tasseling (0.100), days to silking (0.026), and days to maturity (0.024). Only one character cob dismeter has negative value of 'r' (-0.010) with leaves per plant. No character is showing good correlation with number of green leaves per plant.

Days to maturity of «Grop:

This character is the positively significantly correlated with days to tasseling (0.450), days to silking (0.355) and has only positive value of 'r' with

green leaves per plant (0.034), number of cobs per plant (0.026) and cob length (0.003). This character found to be negatively correlated with 100 grain weight (-0.217), yield per plant (-0.185), plant height (-0.068) and cob diameter (-0.016). However the days to tasseling silking have a fair value of 'r' with days to maturity of the exop.

Number of Cobs per Plant:

plant (0.209), 100 grain weight (0.291), number of leaves per plant (0.280), cob length (0.266), plant height (0.165), and days to maturity (0.026). The first two characters are significant at 5% level. Och diameter (-0.363), days to silking (-0.164), days to tasseling (-0.112), showed negative correlation value. Yield of the plant is showing high degree of association with cobs per plant.

Ood Length:

This character is positively correlated with yield per plant (0.481), leaves per plant (0.269), 100 grain weight (0.266), cobs per plant (0.246), plant height (0.173) and days to maturity (0.008). This character is also negatively correlated with days to silking (-0.080), days to silking (-0.084) and cob dismeter (-0.013). Oob length has got a significant effect on yield per plant.

Cob Diameter:

with 100 grain weight (0.261), yield per plant (0.208).

and plant height (0.182). Other characters are negatively correlated as days to miking (-0.724), number of
cobs per plant (0.353), days to tasseling (-0.189),
days to maturity (-0.016), cob length (-0.013), and leaves
per plant (-0.010). The characters days to miking and
number of cobs per plant are significant at 5% level.

Weight of 100 grain seeds:

of the plant (0.489), plant height (0.408), number of cobs per plant (0.291), leaves per plant (0.280), sob length (0.265) and cob dismeter (0.261). The yield per plant and plant height are significant at 5% level. Some of the characters are negatively correlated as days to tasseling (-0.460), days to silking (-0.393) days to maturity of crop (0.217). The days to tasseling and silking are significant at 5% level. The character 100 grain weight has get significant positive correlation value with yield.

Meld Per Plant:

This character shows positive significant value of 'r' with 100 grain weight (0.489) cob length (0.431), number of cobs per plant (0.399), and only

positively correlated with cob diameter (0.208), leaves per plant (0.205) and plant height (0.159),. Tield per plant is negatively correlated with days to tesseling (~0.236), days to milking (~0.233) and days to maturity (~0.186). The days to tesseling of crop has significant value of 'r' at 5% level. Yield per plant is showing a high correlation with cobs per plant, cob length, weight of 100 grain seeds and days to tesseling and silking are negatively correlated.

Correlation Studies of Various Characters in Indred Lines and their \mathbf{F}_1 Crosses are shown in table No. 6:

The number of green leaves per plant is positively correlated and significant with each other (0.332), while other character like days to tasseling (0.826), days to maturity (0.218), cob length (0.200), days to Silking (0.142), loo grain weight (0.126), and sob dissector (0.102), are positively correlated smong each other. Surprisingly the yield (-0.007), number of cobs (-0.036) and plant height (-0.133) were negatively correlated.

PARTIAL CORRELATION:

Plant height (B), Number of green leaves per plant(C) and days to maturity (D), have been used to study the partial coefficient of correlation. In the case of Inbreds (Table No.5) have been given.

The maximum effect of yield has been shown by plant height ('r' = 0.641) followed by green leaves per plant ('r' = 0.861), and days to maturity ('r'= 0.010). The results with plant height are significant at 8% level.

In the case of F_1 hybrids (Table No.5) on the other hand yield is being effected by green leaves per plant ('r' = 0.688), followed by days to maturity (0.414) and plant height ('r' = 0.206). In each case the remaining two factors effect were held constant.

The Heterotic Effect of six characters on 45 single Crosses and their results (Table No.12):

The maximum effect of heterosis have been noticed in the case of yield per plant, followed by Plant height, 100 grain weight, cob length, cob dismeter, and days to maturity.

In the case of the plant height, the cross U201 x U202 is showing an increase of 39.9% on the mean

of the parents and 38.6% over the superior parent followed by the cross USO4 x UEO9 which is showing an increase of 33.1% and 35% respectively. There is no heterotic effect in some of the crosses like UEO7 x UEO3.

In the case of 100 grain weight of seeds, the maximum effect of heterosis was 38.0% and 36.4% in cross was 09.0% and 36.4% in cross was 09.0% and 37.8% respectively. The three crosses as U9 x U202 u202 x U203 x U201 are not showing any effect of heterosis while the crosses like U202 x U205 is showing the negative value as 14.7 and 13.0% respectively.

cob length is showing the maximum value for heterotic effect as 64.4 and 60.0% respectively in crosses like U304 x U209, and U209 x U307 respectively.

opb diameter has maximum value for heterotic effect as 21.2% and 20.4% respectively in cross U207 x U215, followed by 20.6% in U9 x U204. No effect was seen in erosses like U201 x U210, U201 x U212. and U208 x U201.

Days to maturity did not show much effect.

As regards yield per plant is concerned cross U205 x U203 is showing 236.1% effect followed by the cross U201 x U218 as 207.6%. Many of the crosses are not showing any effect of haterosis.

GETERAL AND SPECIFIC COMBINING ABILITY:

The general and specific combining ability have been calculated for 3 groups consisting of 6 inbred lines each by Sprauge & Tatum's method (1942), Table No. 9, 10 and 11.

Group I:

The variance for general combining ability is largest for inbred UEOE (59.3), followed by UELE(26.2) and UEOL (0.50). For rest of the inbreds used, wf9, UELO UEOL, shows practically no variance.

The variance for specific combining ability have been found practically in all inbred lines, the maximum variance being 330.0 shown by USIO, followed by wf9 (270.06), USOI (230.88), UEI2 (144.1), UEO2 (113.70), and UEOI (70.66).

Group II:

The variance for general and specific ability is maximum in USO2 (SEL.4) and for USO3 (608.10) respectively.

Croup III:

The variance for general combining ability has been obtained maximum in inbred U307 (162.3) followed

by U304 (101.0), U208 (74.3), U209 (61.8) Uwf9 (4.44); and finally for U201 (4.0) respectively whereas in specific combining ability the maximum varience have been obtained in U201 (280.51), followed by U209 (254.0); U208 (193.8), U307 (180.62) Uwf9 (30.78) and for U304 (15.76) respectively.

DISCUSSIONS

The present study was taken to find out the association between yield and certain plant characters in maise. The ten plant characters studied could easily be grouped into three, maturity group, vegetative group and ear group.

In order to find out how different characters were interrelated and their association with yield the coefficient of correlations were found between these ten characters of Inbred lines, their hybrids and the Inbreds Vs crosses respectively.

The most important plant characters directly related to yield were ear characters. The statistical analysis showed that the inbreds and excesses differed significantically in days to silking, Plant height, cobs per plant and yield per plant. These differences could camily be explained on gene action, physiological conditions and the effects of environments.

In Inbred lines the maturity characters, viz. days to tasseling and days to maturity showed high positive correlation between each other as well as with yield. The days to silking, showed positive correlation with days to tasseling and negative correlation with yield of the plant. The days to tasseling and days to silking were taken as indicators of the actual maturity period of the crop and thereby determining the yield.

a negative correlation between days to silking and yield in maise. Similar results were observed by Jenkins (1920) also. He later pointed out that late maturity in inbreds was an indication of lower yield which he explained was due to the presence of delitrious characters in them. The results regarding the maturity characters were in agreement with that of Swing (1910), Wolfe (1924) and Jenkins (1929).

Maturity characters studied in F₁ crosses were found to be positively correlated with days to tasseling, days to silking, while days to maturity of crop were negatively correlated with yield working with days to tasseling that the character was positively correlated with days to silking and days to maturity on the other hand days to silking were found to be negatively correlated with days to maturity of Crop.

negative correlation was found between days to tasseling and days to silking with yield the hybrid must be an early maturity. Kempton (1926) made certain correlation studies with makes hybrids and reported that early flowering varieties were more productive. Murthy and hoy (1967) found negative correlation between yield and days to milking, and a positive correlation between days to tasseling and yield in some open pollinated varieties of Indian makes. However, Berkner's (1939) findings were completely opposite to Jenkin's (1939) findings and others. However, between the constitution between days to concluded that there would be no correlation between days to naturity and yield.

In Inbred lines Ewing (1910), Jorgenson and Brewbaker (1927), Jenkins (1929), Hays and Jhonson (1939), reported that height of the plant and total leaf area were positively correlated with yield of the plant.

while studying the correlations among the plant height and yield in hybrids, Jenkins (1929) reported that yield was positively correlated with plant height. This indicated that vigour of the plant determined the yield. Murthy & Roy (1967) also found a positive correlation with plant height and yield. Similar results were obtained by Jorgenson & Brewbaker (1927), Hays & Jhonson (1939).

omprising of cobs per plant, sob length, cob dismeter, and 100 grain weight showed positive correlation with yield in Inbred lines. Love (1912), Biggar (1919), Richey (1926), Jonkins (1929) had also reported the positive correlation between cobs per plant and yield, cob length and yield similar results were showed by Davenport (1897) and Wolfe (1924). Montogomery (1911), Mc Call & Wheeler (1913), Love & Wents (1917), Robinson Comstook and Harvey (1951), found positive correlation between cob dismeter and yield. For 100 grain weight a positive value of correlation with yield was obtained by Granthium (1957).

In F₁ excesses cobs per plant, cob length and loo grain weight showed positive correlation with yield and similar results were reported by Mc Call and Wheeler (1913), Love & Wents (1917), Howard (1919), Milsson Leismer (1927), Jenkins (1929) and Murthy & Roy (1957).

vely correlated with their yields of hybrid progenies.
Similar results had been reported by michey (1924), Hays (1926), Mangelsdorf (1926), Kiesselbach (1922) reported that a general relationship exist between yielding ability of inbred parent and their progeny, however there was a few exception to it. Richey & Mayor (1924) were just opposite to the findings of Milsson Leismer (1927) and

Jorgenson & Browbeker (1927). They reported correlation between various attributes of inbreds and hybrids which could be used for selection. A positive value of correlation was also obtained between yield of inbred line and their F1 crosses.

The most comprehensive correlation studied were worked by Jenkins (1929). He calculated the 'r' values between various characters in inbreds and in their hybrid progenies. He obtained positive correlation in days to tasseling, days to silking, ears per plant, ear length, ear diameter, and negative correlation in lant height and yield. The results obtained in present study agree to with that of Richay (1924) and Jenkins (1929).

Partial correlations were computed between yield and each of 3 characters vis. Plant beight, number of green leaves per plant and days to maturity. These characters were selected as each of them was correlated with yield, whereas among themselves they showed a little or no correlation.

In ease of Ibbred lines the partial correlation was uniform with each of the independent variable. viz. plant medget, leaves per plant and days to maturity. however, the maximum relation was mit plant height. This indicated that plant height had direct effect on yield. Similar results were obtained by Jenkins (1929). In I crosses the yield had directly effected by green leaves per plant, followed by days to maturity and plant height, when other factors in each comparison were kept constant.

On the other hand Murthy & Roy (1987) studying partial correlation between yield and five other characters found plant height to have the minimum effect on yield.

In the 45 crosses of mains (Zea mays L.), studied marked heterotic effect was observed in number of morphological characters such as plant height, coblength, cob dismeter, 100 grain weight and finally the yield. In some of the cases the increase in yield incre varied from 20.1 to 236.1 per cent over the mean of the parents as well as over the superior parent followed by plant height and cob length.

Pal (1956) studied the heterotic effect on plant height, leaves per plant, days to silking and days to tasseling in mains and concluded that maximum result of heretonis could be obtained in the crop.

COMBINING ARLITY

Modern corn breeding depends upon the isolation of commercially acceptable inbred lines as reported by Sprauge & Tatum (1942) and these inbred lines should be good combiners.

and Specific combining ability on the basis of gene action involved and they said that predominantly general combining ability was due to additive gene action, while the Specific combining ability right be the result of unity type of non additive gene action i.e. Dominance, ability or the interaction between gene and environment.

In the present study the varience for Specific combining ability was found greater than the varience for general combining ability indicating that non additive gene action taking place. In two of the inbred lines USOS and USOA the varience for general combining ability was greater than the specific combining ability. This indicated that here additive gene effect was more important. The results reported by this study were more or less contrary to the results reported by Sprauge & Tabun (1942). They found that variance for general combining ability was higher than variance for specific combining ability in their inbred lines used.

They further said that variance for General combining ability for previously untested lines was higher, then those of Specific combining ability for previously tested lines. The difference might be also due to the genetic constituents of the Inbred lines used. Thus they had emphasized more on specific combination of the lines.

ment can be stated as: (1) The results were based on a single experiment which might not be considered reliable, as Rojas & Sprange (1952) clearly stated that estimates of relative magnitude of general and specific combining ability from individual experiment might be of limited value and (2) the number of Inbred lines included in our study were less.

Surciaity & Conclusions

The 15 inbred lines and their 46 single orosses produced by the standard methods at Botanical Garden of Rajasthan College of Agriculture, Udaipur, were studied in respect of different plant characters with the view to find out their association with the yield of the plant.

- 2. The interrelationships between various characters including yield were studied by mame of total as well as partial correlation coefficient.
- 3. The maturity characters were found to be correlated with plant height and leaves per plant and with some of the ear characters like cob length, cob diameter and low grain weight in inbreds and hybrid proganies.
- 4. Negative correlations were observed between yield and days to silking (-835), days to tasseling (-0.386) and days to maturity (-0.185).

- 55 -

5. Positive correlation between Inbreds and their hybrids with regard to green leaves per plant (0.332), days to tesseling (0.228), days to maturity (0.218), cob length (0.200), and loo grain weight (0.126) was observed. However the yield, (-0.007), plant height (-0.133) and cobs per plant (0.036) were negatively correlated with each other.

- between yield and each of the three characters appearately in inbreds and hybrids vis. Plant height, number of green leaves per plant and days to maturity of crop. In Inbreds yield was found to be correlated more with plant height followed by leaves per plant and days to maturity, while in hybrid yield was correlated with Leaves, days to maturity and plant height.
- 7. Variance for specific combining ability was greater than variance of general combining ability in all the three groups. This indicates that selection for specific combining ability could be more effective than the selection for general combining ability in these groups.
- E. Marked effects of haterosis was observed in respect of yield, plant height, cob length, cob diameter and loo grain meight.
- 9. Low or no effect of heterosis was noticed in days to naturity of the plant.

Indexing his minoure gratitudes towards his guide, teacher and professor Dr. H.N. Mehrotra, had of the Department of Agricultural Botany and Plant Pathology, Rajasthan College of Abriculture, Udaipur, who took extra ordinary interest and pains in providing him with his indispensable guidance and it under his worthy guidance that the present work could take this shape.

The sincere regards are also due towards
Associate Professors Shri B.K. Vig and Shri S.N. Chaturvedi
Shri B.K. Kaul and Lecturer Dr. D. Sharma who helped a lot
in proper presentation of the material.

Finally, writer owes a special debt of gratitude to Dr. A. Rathore, Dean, Rajasthan College of Agriculture, Udaipur and Mrs. Rathore, Head of the Department of
Agricultural Economies & Statistics for providing him with
all the required facilities in connection with the
statistical calculation work.
